Abstract	<p>This deliverable discusses the technical details and choices for the implementation of the year-3 validation scenario of the CoDyCo project. The validation scenario aims at verifying the control performances in the case the humanoid robot iCub must balance by means of compliant or dynamical contacts. With <i>dynamical contact</i> we mean that the robot's link in contact with the environment is not fixed with respect to an inertial frame, and the wrench applied to it is not due to a spring-damper system. First, we detail the control algorithm for dealing with a soft carpet underneath the robot's feet. This case study exemplifies the case of a robot interacting with a compliant environment. Then, we present the control algorithm to allow the robot balancing on a semi-cylindrical seesaw. This case study exemplifies the problem of a humanoid robot balancing by means of dynamical contacts. In fact, the robot's feet do not have a constant pose with respect to the inertial frame in this case. Contact and trajectory planning are not part of the scenario.</p>

1 Introduction

Differently from the first and second year validation scenarios, the third year CoDyCo scenario consists in adding compliance and dynamicity of the robot contacts while the humanoid attempts at balancing. This kind of situations have not received much attention from the control community, and the solutions presented in this document are original in several aspects.

As in the previous validation scenarios, the control objective is the regulation of the robot momentum. The rate-of-change of this momentum equals the summation of all external wrenches applied to the system, and controlling the external wrenches to stabilize the robot's momentum is a known control strategy for humanoids when balancing. One of the main difficulties when dealing with compliant and dynamical contacts in this context comes from the fact that the external wrenches may not be instantaneously related to the robot's torques, i.e. the input to the system. This is the case, for instance, of a humanoid standing on two springs, which exert forces on the robot's feet that depend on the relative compressions only.

There may be some particular soft terrains, however, that exert forces and torques not only depending on the relative compressions, but also on the robot's joint torques. In these cases, the soft terrain is subject to some rigid constraints that may allow the control of the robot's momentum through the external forces, which thus depend on the joint torques. This is the case of a thin, highly damped carpet, which can be modeled, in the first approximation, as a continuum of vertical springs. Each of these springs is assumed to compress vertically only, and the other degrees of freedom are rigidly constrained, thus creating the aforementioned relation between external forces and joint torques. The first experimental demo during the review meeting consists of showing the humanoid robot iCub while it balances on a soft carpet of the above kind.

We then go one step further and present control algorithms to deal with *dynamical* contacts. The application scenario of the controller consists of the humanoid robot iCub balancing on a semi-cylindrical seesaw. In this case, the contacts between the robot and its environment are subject to the seesaw dynamics, and the control of the robot is particularly challenging.

The iCub will be torque controlled and the controller assumes that desired torques are exactly executed by a lower level torque control. Dynamics will be computed with a custom library, iDynTree¹, built on top of KDL².

The deliverable is organized as follows. Section 2 presents the notation, the robot equations of motion, and recalls on the controller implemented for the first and second year validation scenario. Section 3 discusses the modeling and control design in the case a humanoid must balance on a thin, compliant carpet. Section 4 presents the control design in the case the humanoid must balance on dynamical contacts, and the theory is applied to the case of balancing on a seesaw. Section 5 presents the estimation algorithms used to estimate the floating base of the robot and the compliance of the thin carpet used for the validation scenario.

2 Background

2.1 Notation

Throughout the paper we will use the following definitions:

- \mathcal{I} denotes an inertial frame, with its z axis pointing against the gravity. We denote with g the gravitational constant.
- $e_i \in \mathbb{R}^m$ is the canonical vector, consisting of all zeros but the i -th component which is one.
- Given two orientation frames A and B , and vectors of coordinates expressed in these orientation frames, i.e. ${}^A p$ and ${}^B p$, respectively, the rotation matrix ${}^A R_B$ is such that ${}^A p = {}^A R_B {}^B p$.
- $1_n \in \mathbb{R}^{n \times n}$ is the identity matrix of size n ; $0_{m \times n} \in \mathbb{R}^{m \times n}$ is the zero matrix of size $m \times n$ and $0_n = 0_{n \times 1}$.
- We denote with $S(x) \in \mathbb{R}^{3 \times 3}$ the skew-symmetric matrix such that $S(x)y = x \times y$, where \times denotes the cross product operator in \mathbb{R}^3 .

2.2 Robot equations of motion

We assume that the robot is composed of $n + 1$ rigid bodies – called links – connected by n joints with one degree of freedom each. In addition, we also assume that the multi-body system is *free floating*, i.e. none of the links has an *a priori* constant pose with respect to the the inertial frame. This implies that the multi-body system possesses $n + 6$ degrees of freedom. The configuration space of the multi-body system can then be characterized by the *position* and the *orientation* of a frame attached to a robot's link – called *base frame* \mathcal{B} – and the joint configurations. More precisely, the robot configuration space is defined by

$$\mathbb{Q} = \mathbb{R}^3 \times SO(3) \times \mathbb{R}^n.$$

An element of the set \mathbb{Q} is then a triplet

$$q = ({}^{\mathcal{I}} p_{\mathcal{B}}, {}^{\mathcal{I}} R_{\mathcal{B}}, q_j),$$

where $({}^{\mathcal{I}} p_{\mathcal{B}}, {}^{\mathcal{I}} R_{\mathcal{B}})$ denotes the origin and orientation of the *base frame* expressed in the inertial frame, and q_j denotes the *joint angles*. It is possible to define an operation associated with the set \mathbb{Q} such that this set is a group. More precisely, given two elements q and ρ of the configuration space, the set \mathbb{Q} is a group under the following operation:

$$q \cdot \rho = (p_q + p_\rho, R_q R_\rho, q_j + \rho_j). \quad (1)$$

Being the direct product of Lie groups, the set \mathbb{Q} is itself a Lie group. The *velocity* of the multi-body system can then be characterized by the *algebra* \mathbb{V} of \mathbb{Q} defined by: $\mathbb{V} = \mathbb{R}^3 \times \mathbb{R}^3 \times \mathbb{R}^n$. An element of \mathbb{V} is then a triplet

$$\nu = ({}^{\mathcal{I}} \dot{p}_{\mathcal{B}}, {}^{\mathcal{I}} \omega_{\mathcal{B}}, \dot{q}_j),$$

where ${}^{\mathcal{I}}\omega_B$ is the angular velocity of the base frame expressed w.r.t. the inertial frame, i.e. ${}^{\mathcal{I}}\dot{R}_B = S({}^{\mathcal{I}}\omega_B){}^{\mathcal{I}}R_B$.

Although the above digression on the robot configuration space may sound pedantic and marginal, let us observe that the choice of the group operation in (1) implies that an element $\nu \in \mathbb{V}$ is composed of \dot{p} , i.e. the time derivative of the origin of the floating base frame. Other choices for the group operation would imply a different algebra and, consequently, a different representation of the system's *velocity*.

We also assume that the robot is interacting with the environment through n_c distinct contacts. Applying the Euler-Poincaré formalism [1, Ch. 13.5] to the multi-body system yields the following equations of motion:

$$M(q)\dot{\nu} + C(q, \nu)\nu + G(q) = B\tau + J^\top(q)f \quad (1a)$$

$$J^\top(q)f := \sum_{k=1}^{n_c} J_{C_k}^\top f_k \quad (1b)$$

where $M \in \mathbb{R}^{n+6 \times n+6}$ is the mass matrix, $C \in \mathbb{R}^{n+6 \times n+6}$ is the Coriolis matrix, $G \in \mathbb{R}^{n+6}$ is the gravity term, $B = (0_{n \times 6}, 1_n)^\top$ is a selector matrix, τ are the internal actuation torques, and f_k denotes an external wrench applied by the environment on the link of the k -th contact. We assume that the application point of the external wrench is associated with a frame \mathcal{C}_k , which is attached to the robot's link where the wrench acts on and has its z axis pointing as the normal of the contact plane. Then, the external wrench f_k is expressed in a frame whose orientation coincides with that of the inertial frame \mathcal{I} , but whose origin is the origin of \mathcal{C}_k , i.e. the application point of the external wrench f_k . The Jacobian $J_k = J_k(q)$ is the map between the robot's velocity ν and the linear and angular velocity ${}^{\mathcal{I}}v_{C_k} := ({}^{\mathcal{I}}\dot{p}_{C_k}, {}^{\mathcal{I}}\omega_{C_k})$ of the frame \mathcal{C}_k , i.e.

$${}^{\mathcal{I}}v_{C_k} = J_{C_k}(q)\nu. \quad (2)$$

The Jacobian has the following structure.

$$J_{C_k}(q) = \begin{bmatrix} J_{C_k}^b(q) & J_{C_k}^j(q) \end{bmatrix} \in \mathbb{R}^{6 \times n+6}, \quad (2a)$$

$$J_{C_k}^b(q) = \begin{bmatrix} 1_3 & -S({}^{\mathcal{I}}p_{C_k} - {}^{\mathcal{I}}p_B) \\ 0_{3 \times 3} & 1_3 \end{bmatrix} \in \mathbb{R}^{6 \times 6}. \quad (2b)$$

Lastly, we assume that rigid contacts may occur between the robot and the environment. The rigid contacts are assumed to be due to the rubbing of two flat surfaces belonging to the robot and to the environment, respectively. The constraint associated with the rigid contact is modeled as a kinematic constraint that forbids any motion of the frame \mathcal{C}_k , i.e. $J_{C_k}(q)\nu = 0$.

2.3 The controller for the first and second year validation scenario

The control objective for achieving balancing on either one foot or two feet has been the following ones since the beginning of the project:

1. Stabilization of the robot's momentum (expressed at the center-of-mass and with the inertial frame orientation), which is defined by

$$H = \sum H_i = \begin{pmatrix} m\dot{x} \\ H_\omega \end{pmatrix},$$

Figure 1: A screen-shot of the one-foot balancing demo

with H_i the momentum of each link composing the multi-body system, m the total mass of the robot, $x \in \mathbb{R}^3$ the position of the robot center-of-mass, and H_ω the angular momentum of the multi-body system. Let us recall that contrary to the case of a single rigid body, the possibility of expressing the angular momentum H_ω in terms of a proper angular velocity is still open. For this reason, we won't refer to a *robot angular velocity* when stabilizing the humanoid angular momentum.

The control of the robot momentum is achieved assuming the contact wrenches as a virtual control input in the dynamics of H . For instance, assuming that the robot is balancing on two feet, two external wrenches $f_L \in \mathbb{R}^6$ and $f_R \in \mathbb{R}^6$ act on the left and right foot, respectively. Then, one has

$$\dot{H} = mg + {}^cX_L f_L + {}^cX_R f_R = mg + \begin{pmatrix} {}^cX_L & {}^cX_R \end{pmatrix} f, \quad (3)$$

where ${}^cX_L, {}^cX_R \in \mathbb{R}^{6 \times 6}$ are two proper projection matrices, and $f := (f_L^\top, f_R^\top)^\top$. Since f is assumed to be a control input, one can choose it so that $\dot{H} = \dot{H}^*$, where \dot{H}^* ensures that $x \rightarrow x_d$ and $H_\omega \rightarrow 0$. Clearly, at this level, one is left with a six-dimensional redundancy of the control input. This redundancy is exploited to minimize joint torques.

2. In the null space of the above task, we want the robot to assume a desired joint configuration, while having also some compliance. This is achieved by means of a postural task at the joint torque level, which exploits a proportional-derivative plus gravity compensation control strategy for stabilizing a desired joint reference.

In the language of the *Optimization Theory*, the above control objectives can be formulated as follows.

$$f^* = \underset{f}{\operatorname{argmin}} |\tau^*(f)| \quad (4a)$$

s.t.

$$Cf < b \quad (4b)$$

$$\dot{H}(f) = \dot{H}^* \quad (4c)$$

$$\tau^*(f) = \underset{\tau}{\operatorname{argmin}} |\tau(f) - \tau_0(f)| \quad (5)$$

s.t.

$$\dot{J}(q, \nu)\nu + J(q)\dot{\nu} = 0 \quad (5a)$$

$$\dot{\nu} = M^{-1}(S\tau + J^\top(q)f - h(q, \nu)) \quad (5b)$$

$$\tau_0 = \bar{h} - \bar{J}_j^\top f - K_p(q_j - q_j^{des}) - K_d(\dot{q}_j - \dot{q}_j^{des}) \quad (5c)$$

For the sake of completeness, in the above optimization problem one has

$$\dot{H}^* = \begin{pmatrix} m(\ddot{x}_d - k_p(x - x_d) - k_d(\dot{x} - \dot{x}_d)) \\ -k_\omega H_\omega - k_i \int_0^t H_\omega ds \end{pmatrix} \quad (6a)$$

$$\bar{h} := h_j - M_{bj}^\top M_b^{-1} h_b \quad (6b)$$

$$\bar{h} := \begin{pmatrix} h_b \\ h_j \end{pmatrix} = C(q, \nu)\nu + G(q), \quad h_b \in \mathbb{R}^6 \quad h_j \in \mathbb{R}^n \quad (6c)$$

$$\bar{J} := J_j - J_b^\top M_b^{-1} M_{bj} \quad (6d)$$

$$M = \begin{pmatrix} M_b & M_{bj} \\ M_{bj}^\top & M_j \end{pmatrix} \quad M_b \in \mathbb{R}^{6 \times 6} \quad M_{bj} \in \mathbb{R}^{6 \times n} \quad M_b \in \mathbb{R}^{n \times n} \quad (6e)$$

Note that the additional constraint (4b) ensures that the desired contact wrenches f belong to the associated friction cones. Once the optimum f^* has been determined, the input torques τ are obtained by re-using the expression (5), i.e.

$$\tau = \tau^*(f^*) \quad (7)$$

Now, by direct calculations one can verify that the solution to the problem (5) is an affine function versus the desired wrenches f , i.e. $\tau^* = A(q, \nu)f + b(q, \nu)$, where $A \in \mathbb{R}^{n \times 12}$ and $b \in \mathbb{R}^n$ two proper matrices. This leads to the following simplification of the optimization problem

$$f^* = \underset{f}{\operatorname{argmin}} |\tau^*(f)| \quad (8a)$$

s.t.

$$Cf < b \quad (8b)$$

$$\dot{H}(f) = \dot{H}^* \quad (8c)$$

$$\tau^*(f) = A(q, \nu)f + b(q, \nu) \quad (8d)$$

The above control algorithm has run at both review meetings of the CoDyCo project.

Figure 2: A compliant carpet subject to a uniform force distribution

3 Modelling and control design for a humanoid balancing on a thin carpet

This section discusses the modification of the control algorithm (4) for dealing with compliant contacts. Prior to the control design, however, we present a simple model for the carpet.

3.1 Modelling

To introduce the reader to the model of a compliant carpet, we first consider the planar case, and then address the three-dimensional case.

3.1.1 A case study: the planar case

Figure 2 shows a uniform force distribution acting on a compliant carpet of height h . The resultant force due to the distribution is denoted by F . The force distribution induces a compression of the compliant carpet and, assuming uniform carpet characteristics, the compression is equally distributed. So, the carpet is horizontal even after the compression due to the force distribution. Now, assume that the mapping $F : z_M \rightarrow F_E$ is known – or properly estimated – in the case shown in Figure 2. The following details how to evaluate the resultant force and torque acting from the carpet to the contact surface when it is not uniformly compressed. To this purpose, we make the following assumptions.

Assumption 1. *Throughout the paper, we assume the following.*

1. *The carpet characteristics are isotropic.*
2. *The soft carpet can be approximated as a continuum of springs. In addition, each infinitesimal spring can exert only a vertical force.*
3. *An off-line estimation procedure provides us with the mapping $F = F_E(z_M)$ when a uniform force distribution $f(\cdot)$ is applied to the carpet.*

Let l denote the length of the compliant carpet subject to the uniform force distribution. As a consequence of assumptions 1.1 and 1.3, one has:

$$F_E(z_M) = \int_a^b f(z_M) dx = f(z_M)l. \quad (9)$$

So, we can evaluate the force distribution $f(z)$ from the estimated force $F_E(z_M)$,

$$f(z) = \frac{F_E(z)}{l}. \quad (10)$$

Then, Eq. (9) can be used to evaluate the total force applied from the carpet to a generic contact surface, i.e.

$$F = \int_a^b f(z(x)) dx, \quad (11)$$

with $z(x)$ a proper function describing the shape of the contact surface on a domain $x \in [a, b]$. Also, in view of the assumption 1.2, the torque about a point located at $x = \bar{x}$ of the carpet can be easily computed as:

$$M = \int_a^b f(z(x))(x - \bar{x}) dx. \quad (12)$$

3.1.2 The case of a flat contact surface and a linear force distribution

Assume that the flat surface in Figure 2 bends as shown in Figure 3. Then, its shape can be characterized by a line of slope $\tan(\theta)$, i.e

$$z(x) = z_M + \tan(\theta)(x - x_M), \quad (13)$$

with (x_M, z_M) the coordinates of the central point of the flat plate. In addition, assume also that the estimated force $F = F_E(z_M)$ is linear with respect to the carpet's compression, i.e.

$$F_E(z_M) = K(h - z_M),$$

which implies

$$f(z) = k(h - z), \quad (14)$$

with $k := K/l$. Then, the total force and torque exerted from the compliant carpet to the flat surface is given by (11) and (12) evaluated with (14) and (13), i.e.

$$F = \int_{x_M - \frac{l}{2} \cos(\theta)}^{x_M + \frac{l}{2} \cos(\theta)} f(z(x)) dx = kl \cos(\theta) (h - z_M) \quad (15a)$$

$$\begin{aligned} M &= \int_{x_M - \frac{l}{2} \cos(\theta)}^{x_M + \frac{l}{2} \cos(\theta)} f(z(x))(x - \bar{x}) dx \\ &= kl \cos(\theta) \left[(h - z_M) (x_M - \bar{x}) - \frac{l^2}{12} \sin(\theta) \cos(\theta) \right] \end{aligned} \quad (15b)$$

Figure 3: A compliant carpet subject to a non-uniform force distribution

The process of finding the solutions to the above integral is simplified by applying the variable transformation $\xi = x - x_M$, which renders the limits of integration equal to $-0.5l \cos(\theta)$ and $0.5l \cos(\theta)$. This hint is used for calculating the integrals in the more-complex 3-D case.

Note that if the torque M is expressed with respect to the central point (x_M, z_M) of the plate, one has:

$$F = kl \cos(\theta) (h - z_M) \quad (16a)$$

$$M = -k \frac{l^3}{12} \sin(\theta) \cos^2(\theta) \quad (16b)$$

As shown in Figure 3, positive angles θ produce negative torques,

3.1.3 The three-dimensional case

Analogously to the planar case, this section addresses the modeling of the forces and torques applied from a compliant carpet to a contact surface by considering the three-dimensional case. To this purpose, we still assume that Assumption 1 holds, modulo straightforward modifications for handling the three-dimensional case. In particular, we assume that an estimation procedure is performed when the contact surface is a flat, rectangular plate of length l and width d – see Figure 4. In addition, we also assume that the estimation procedure consists of applying a uniform force distribution so that the flat plate compresses the carpet uniformly. Hence, the estimated force takes the following form:

$$F_E(z) = e_3 \int_{x_0}^{x_1} \int_{y_0}^{y_1} f(z) dx dy = f(z) l d e_3, \quad (17)$$

with $f(z)$ the vertical force distribution per surface. Hence, the force distribution can be evaluated as follows:

$$f(z) = \frac{|F_E(z)|}{ld}. \quad (18)$$

In light of the above, the force and torque due to a generic contact surface is given by:

$$F = e_3 \int \int_D f(z) dx dy, \quad (19a)$$

$$M = \int \int_D f(z) S(p - \bar{p}) e_3 dx dy, \quad (19b)$$

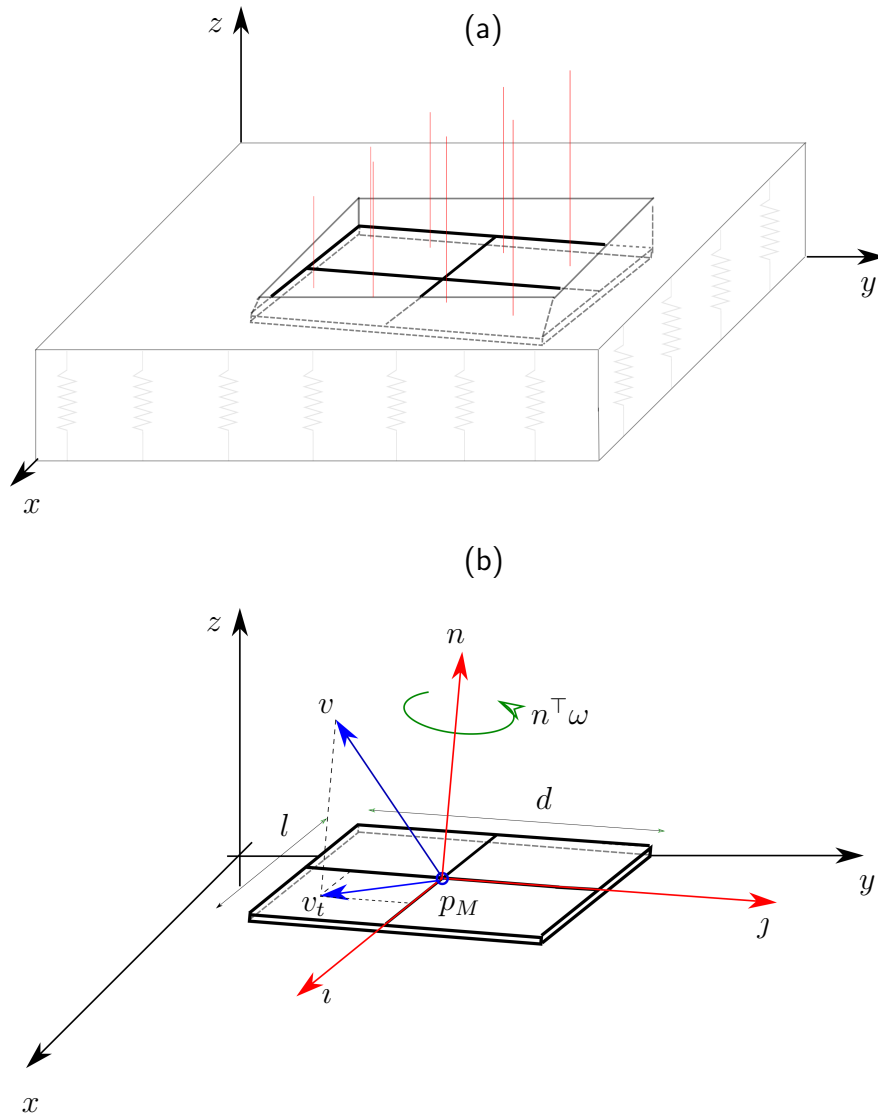

Figure 4: A compliant carpet subject to a non-uniform force distribution

with $p = (x \ y \ z)^\top$ a point of the contact surface, $\bar{p} = (\bar{x} \ \bar{y} \ \bar{z})^\top$ the point w.r.t. which the torque is expressed, and $D \subset \mathbb{R}^2$ a proper integration domain associated with the contact surface configuration.

3.1.4 The case of a flat contact surface and a linear force distribution

Assume that the contact surface is flat – see Figure 4 – so it can be characterized by the following equation

$$n^\top p = 0, \quad (20)$$

with $n \in \mathbb{R}^3$ the unit vector perpendicular to the surface.

Lemma 1. Assume that Assumption 1 holds, and that the force distribution $f(\cdot)$ associated with the compliant carpet is linear with respect to the height, i.e.

$$f(z) = k(h - z). \quad (21)$$

Let a flat, rectangular surface, of length l and width d , be in full-contact with the compliant carpet. Then, the force-torque acting on the rectangular surface at the equilibrium configuration is given by:

$$F = kld|n^\top e_3|(h - z_M)e_3 \quad (22a)$$

$$M = S(p_M - \bar{p})F + \frac{kld}{12}|n^\top e_3|S(e_3)\Lambda(i, j)e_3 \quad (22b)$$

with $\Lambda = d^2jj^\top + l^2i^\top$, p_M the central point of the rectangular surface, and i and j two unit, perpendicular vectors parallel to the rectangle's borders associated with the length and the width, respectively.

The proof is given in the Appendix. The above Lemma points out that the total force F depends on the normal n to the plane representing the flat plate, but it does not depend on the angle about this normal (i.e. the yaw angle about the normal n). Clearly, the force F also depends on how much the plate immerses into the soft carpet, and this dependence comes from the term $(h - z_M)$ in Eq. (22a). The expression of the torque M , instead, is the sum of two terms: the torque due to the force F applied at the point \bar{p} plus a term depending only on the relative orientation of the plate w.r.t. the inertial frame. Note that if the plate is parallel to the plane $x - y$ of the inertial frame, then $i^\top e_3 = 0$ and $j^\top e_3 = 0$. As a consequence, the second term on the right hand side of (22) is equal to zero, and so is the momentum M when expressed with respect to p_M (i.e. $\bar{p} = p_M$).

3.1.5 Constraints associated with the flat plate due to friction

Consider Figure 4, where $v \in \mathbb{R}^3$ denotes the velocity of the point p_M , and $\omega \in \mathbb{R}^3$ the angular velocity of the flat plate, both expressed with respect to the inertial frame. Then, it is reasonable to assume that friction effects forbid any rotation of the plate about the axis n as long as friction forces belong to the associated friction cones, i.e. $n^\top \omega = 0$. In addition, it is also reasonable to assume that friction effects forbid the velocity of any point of the plate to be tangential to the plate itself. It is straightforward to verify that the velocity of any point p of the flat plate has null tangential velocity if and only if the velocity of the point p_M has null tangential velocity when $n^\top \omega = 0$. In light of the above, we assume that as long as friction forces belong to the associated friction cones, one has:

$$i^\top v = 0 \quad (23a)$$

$$j^\top v = 0 \quad (23b)$$

$$n^\top \omega = 0 \quad (23c)$$

The above equations point out that the flat plate can rotate only about the axes i and j , and can also go "up-and-down" due to the compliance of the carpet. When coming to practice,

however, it is also reasonable to assume that the vertical speed of the point p_M is equal to zero, i.e.

$$e_3^\top v = 0 \quad (24)$$

Let us justify this additional hypothesis. Eq. (22a) shows that the vertical force at the equilibrium configuration exerted from the carpet to the plate is given by

$$F_z = kld|n^\top e_3|(h - z_M).$$

Now, without loss of generality, assume that the point p_M is the plate's center of mass. Then, the force balance along the z axis writes:

$$m_p \ddot{z}_M = -k_v \dot{z}_M + kld|n^\top e_3|(h - z_M) - m_p g$$

where m_p is the mass of the plate, and k_v the viscous coefficient associated with the compliant carpet. In particular, thin compliant carpet are typically associated with very high value of k_v , which implies fast convergence of the plate vertical velocity to zero, i.e. $\dot{z}_M \rightarrow 0$. Also, from the above equation, it is clear that at the equilibrium configurations with a flat plate almost parallel to the ground, i.e. $|n^\top e_3| \approx 1$, one has

$$z_M \approx h - \frac{m_p g}{kld}.$$

Since the weight of the plate is constant, then the height z_M converges to the same value independently of an external, vanishing perturbation applied to the plate. This fact combined with the high value of carpet's damping justify the assumption (24).

Note that the constraints (23) (24) can be compactly written as:

$$H(\iota, j, n)v = 0, \quad (25)$$

where

$$H(\iota, j, n) := \begin{pmatrix} \iota^\top & 0_{1 \times 3} \\ j^\top & 0_{1 \times 3} \\ e_3^\top & 0_{1 \times 3} \\ 0_{1 \times 3} & n^\top \end{pmatrix} \quad (26a)$$

$$v := \begin{pmatrix} v \\ \omega \end{pmatrix} \quad (26b)$$

3.1.6 Kinematic constraints and contact forces associated with the robot's feet

Assume that the robot is balancing on both feet, underneath which there is the compliant carpet characterized by the equations presented above. In view of Eqs. (26), the constraints acting on both feet can be compactly written as:

$$\bar{H}v_f = 0, \quad (27)$$

with

$$\bar{H} = \begin{pmatrix} H(\iota_L, j_L, n_L) & 0_{4 \times 6} \\ 0_{4 \times 6} & H(\iota_R, j_R, n_R) \end{pmatrix} \quad (28a)$$

$$v_f = \begin{pmatrix} v_L \\ v_R \end{pmatrix}, \quad (28b)$$

and (\imath_L, j_L, n_L) and (\imath_R, j_R, n_R) two frames attached to the left and right foot, respectively (as indicated in Figure (4)b and v_L and v_R the linear and angular velocity of the central point of the robot's feet, respectively. Now, the feet velocity v_f can be expressed in terms of the robot velocity ν through its Jacobian, i.e.

$$v_f = J(q)\nu.$$

By substituting the above equation into (25), one obtains

$$\dot{J}_s(q)\nu + J_s(q)\dot{\nu} = 0 \quad (29a)$$

where $J_s(q) := \bar{H}(q)J(q)$. Hence, the constraint equations when the robot stands on a compliant carpet have the same form of those when standing on rigid constraints (compare Eqs. (29) and (5a)). What does change between these two situations is the number of rigid constraints acting on the system. In fact, in the case the robot stands on rigid contacts, one has 12 kinematic constraints, while when the humanoid balances on the soft carpet, one has 8 rigid constraints acting on the system.

The rigid constraints generate eight contact forces $f^{rigid} \in \mathbb{R}^8$, which must be taken into account in the dynamic equation, i.e.

$$M(q)\dot{\nu} + C(q, \nu)\nu + G(q) = B\tau + J_s^\top(q)f^{rigid} + J^\top(q)f^{comp} \quad (30)$$

By combining the above equation with the constraints (29), one can find an expression of the contact forces f^{rigid} , which depend on the torque τ and can be assumed as an artificial control input. Note that the effect of the compliant forces f^{comp} in Eq. (30) is also taken into account. Let $f_L^{comp} \in \mathbb{R}^6$ and $f_R^{comp} \in \mathbb{R}^6$ denote the compliant wrenches acting on the left and right foot, respectively. Assuming that the contact torques in Eq. (22) are expressed w.r.t. the feet central point, i.e. $\bar{p} = p_M$, and that the feet can be approximated as two rectangles of the same dimension, one has

$$f_{comp} = \begin{pmatrix} f_L^{comp} \\ f_R^{comp} \end{pmatrix} = kld \begin{pmatrix} |n_L^\top e_3| (h - z_M^L) e_3 \\ \frac{1}{12} |n_L^\top e_3| S(e_3) \Lambda(\imath_L, j_L) e_3 \\ |n_R^\top e_3| (h - z_M^R) e_3 \\ \frac{1}{12} |n_R^\top e_3| S(e_3) \Lambda(\imath_R, j_R) e_3 \end{pmatrix} \quad (31)$$

with z_M^L and z_M^R the third components of the position vectors p_M^L and p_M^R describing the central points of the feet, i.e. $z_M^L = e_3^\top p_M^L$ and $z_M^R = e_3^\top p_M^R$.

3.2 Control design

Recall that the control objective is the asymptotic stabilization of the robot momentum, the rate of change of which equals the net external wrench acting on the system. In the case the robot is balancing on the compliant carpet described in Section (3.1.4), one then has

$$\dot{H}(f^{rigid}) = mg + ({}^c X_L, {}^c X_R) (\bar{H}^\top(q)f^{rigid} + f^{comp}), \quad (32)$$

where f^{rigid} , being dependent on the input torques τ , can be assumed as a control input in the above dynamics. In light of the above, the control problem (4) is modified as follows to deal with the compliant carpet.

$$f_*^{rigid} = \underset{f^{rigid}}{\operatorname{argmin}} |\tau^*(f^{rigid})| \quad (33a)$$

s.t.

$$C f^{rigid} < b \quad (33b)$$

$$\dot{H}(f^{rigid}) = \dot{H}^* \quad (33c)$$

$$\tau^*(f^{rigid}) = \underset{\tau}{\operatorname{argmin}} |\tau(f^{rigid}) - \tau_0(f^{rigid})| \quad (34)$$

s.t.

$$\dot{J}_s(q, \nu)\nu + J_s(q)\dot{\nu} = 0 \quad (34a)$$

$$\dot{\nu} = M^{-1}(S\tau + J_s^\top(q)f^{rigid} + J^\top(q)f^{comp} - h(q, \nu)) \quad (34b)$$

$$\tau_0 = \bar{h} - \bar{J}_j^\top(\bar{H}^\top(q)f^{rigid} + f^{comp}) - K_p(q_j - q_j^{des}) - K_d(\dot{q}_j - \dot{q}_j^{des}) \quad (34c)$$

Analogously to what we discussed in Section 2.3, the above control problem is equivalent to:

$$f_*^{rigid} = \underset{f^{rigid}}{\operatorname{argmin}} |\tau^*(f^{rigid})| \quad (35a)$$

s.t.

$$C f^{rigid} < b \quad (35b)$$

$$\dot{H}(f) = \dot{H}^* \quad (35c)$$

$$\tau^*(f) = A(q, \nu)(\bar{H}^\top(q)f^{rigid} + f^{comp}) + b(q, \nu) \quad (35d)$$

and once the optimal solution f_*^{rigid} is determined, we apply again Eq. (36) to determine the input torques to the robot. The above control algorithm will be implemented for the third year demo review meeting when the humanoid must balance on two feet and on a compliant carpet.

4 Control design for humanoids balancing on dynamical contacts: the case of balancing on a seesaw

4.1 The equation of motion of the seesaw

The equation of motion of the seesaw are derived by considering it as a rigid body subject to the rolling constraint. Let m_s and I_s denote the mass and the inertia matrix of the seesaw, and $\mathcal{I}v_s$ and $\mathcal{I}\omega_s$ the linear velocity of its center of mass and its angular velocity, respectively. Then, the momentum of the seesaw $H_s \in \mathbb{R}^6$ is defined by

$$H_s := \begin{pmatrix} m_s \mathcal{I}v_s \\ I_s \mathcal{I}\omega_s \end{pmatrix}, \quad (36)$$

Figure 5: The semi-cylindrical seesaw

and the equation of motion are given by

$$\dot{H}_s = \sum_i f_{ext_i} \quad (37)$$

subject to the following constraints

$$\mathcal{I}v_p = 0. \quad (38a)$$

$$\mathcal{I}\omega_s^\top e_2 = 0 \quad (38b)$$

$$\mathcal{I}\omega_s^\top e_3 = 0 \quad (38c)$$

with f_{ext_i} the external wrenches acting on the seesaw (see Figure 5). The kinematic constraints (38) express the following facts:

- The seesaw cannot rotate about the axes e_2 and e_3 of the inertial frame.
- The contact point between the seesaw and the floor possesses null velocity. This, along with the constraints on the seesaw angular velocity, ensures that all points of the contact line between the seesaw and the floor have zero velocity.

The satisfaction of the above constraints is ensured as long as the contact wrench w_c (see Figure 5) belong to the associated friction cones.

4.2 Control design

Consider the robot balancing on the seesaw depicted in Figure 6. Recall that the control objective is the asymptotic stabilization of the robot's momentum H , the rate-of-change of which equals the net external force acting on the system. In the case of the robot balancing on the seesaw, one has:

$$\dot{H} = mg + {}^cX_L f_L + {}^cX_R f_R = mg + ({}^cX_L \quad {}^cX_R) f, \quad (39)$$

where ${}^cX_L, {}^cX_R \in \mathbb{R}^{6 \times 6}$ are two proper projection matrices, and $f := (f_L^\top, f_R^\top)^\top$. Now, we consider the contact forces f as a virtual control input of the above system, which can then

Figure 6: The robot balancing on the semi-cylindrical seesaw

be chosen so as $\dot{H} = \dot{H}^*$. To determine the relation between the contact forces f and the input torques τ , we have to define the constraints acting on the system robot plus seesaw.

To do so, consider, for instance, the left foot. As long as the foot stays in contact with the seesaw, the angular acceleration of the foot equals the angular acceleration of the seesaw. Analogously, the linear acceleration of any point belonging to the foot's sole equals the acceleration of the corresponding point belonging to the seesaw. This latter condition can be imposed by considering one single point of the foot's sole. As a consequence, the feet constraints can be expressed as follows:

$$\dot{J}(q)\nu + J(q)\dot{\nu} = a_c \quad (40)$$

where

$$a_c = \begin{pmatrix} a_L \\ a_R \end{pmatrix} = \begin{pmatrix} \ddot{p}_L \\ \mathcal{I}\dot{\omega}_s \\ \ddot{p}_R \\ \mathcal{I}\dot{\omega}_s \end{pmatrix} \quad (41)$$

and a_L and a_R the linear accelerations of the points p_L and p_R , respectively. Note that the accelerations a_L and a_R can be expressed in terms of the acceleration of the seesaw center of mass G_s through the relation

$$\ddot{p}_L = \mathcal{I}\dot{v}_s + \mathcal{I}\dot{\omega}_s \times (p_L - G_s) + \mathcal{I}\omega_s \times (\dot{p}_L - \mathcal{I}v_s). \quad (42)$$

The accelerations \dot{v}_s and $\dot{\omega}_s$ can be evaluated from the Newton-Euler equation of the

seesaw. By considering Figure 6, one has

$$\begin{aligned}\dot{H}_s &= \frac{d}{dt} \begin{pmatrix} m_s \mathcal{I} v_s \\ I_s \mathcal{I} \omega_s \end{pmatrix} = m_s g + {}^s X_c f_c - {}^s X_L f_L - {}^s X_R f_R \\ &= m_s g + {}^s X_c f_c - ({}^s X_L \quad {}^s X_R) f,\end{aligned}\quad (43)$$

The above balance has been written by considering the fact that the force-torque (at each contact) that the seesaw exerts on the robot is equal and opposite to the force-torque the robot exerts on the seesaw. In view of (40), (41), (42), (43), one has

$$\dot{J}(q)\nu + J(q)\dot{\nu}(\tau, f) = a_c(f) \quad (44)$$

In light of the above, the control problem (4) is modified as follows to deal with the dynamical contacts generated by the seesaw.

$$f^* = \operatorname{argmin}_f |\tau^*(f)| \quad (45a)$$

s.t.

$$Cf < b \quad (45b)$$

$$\dot{H}(f) = \dot{H}^* \quad (45c)$$

$$\dot{H}_s = \dot{H}_s(f, fc) \quad (45d)$$

$$\mathcal{I} v_p = 0 \quad (45e)$$

$$\mathcal{I} \omega_s^\top e_2 = 0 \quad (45f)$$

$$\mathcal{I} \omega_s^\top e_3 = 0 \quad (45g)$$

$$\tau^*(f) = \operatorname{argmin}_\tau |\tau(f) - \tau_0(f)| \quad (46)$$

s.t.

$$\dot{J}(q)\nu + J(q)\dot{\nu}(\tau, f) = a_c(f) \quad (46a)$$

$$\dot{\nu} = M^{-1}(S\tau + J^\top(q)f - h(q, \nu)) \quad (46b)$$

$$\tau_0 = \bar{h} - \bar{J}_j^\top f - K_p(q_j - q_j^{des}) - K_d(\dot{q}_j - \dot{q}_j^{des}) \quad (46c)$$

5 Estimation algorithms

This section discusses the estimation algorithms for both the floating base and the compliance of the soft carpet.

5.1 Estimation of the floating base

5.1.1 Quaternion-based Extended Kalman Filter

The goal of this Kalman Filter is to estimate the orientation of our previously defined world reference frame³ w with respect to the sensor reference $\{s\}$ in the quaternion representation

³Remember it was defined as a right-handed co-ordinate system with the positive x axis pointing to the local magnetic North, positive z pointing up and y according to the right handed system

(radians), i.e. q_w^s . We start with a simplified version of the filter where only a triad of gyroscopes and accelerometers will be used along with a simple model of the process representing solely the orientation to be estimated. In this way, the state of the Kalman Filter will be the quaternion-based orientation of the world w in the sensor reference frame $\{s\}$, i.e.

$$x = q_w^s \quad (47)$$

Where $q = [q_1 \quad q_v]$, $q_1 \in \mathbb{R}$, $q_v \in \mathbb{R}^3$ and $\|q\| = 1$.

Figure 7: Earth-fixed (world) reference frame w and local sensor reference frame $\{s\}$. $R(q_w^s)$ denotes the quaternion-based rotation matrix that rotates the world reference frame w into $\{s\}$.

5.1.2 Discrete Time Process Model

$[x_{k+1} = Ax_k + w_k]$. This model is obtained starting off the continuous time equations relating the quaternion orientation with its derivative resulting in the following differential equation:

$$\dot{q}_w^s(t) = \frac{1}{2}\Omega(\omega^s(t))q_w^s(t) \quad (48)$$

From now on, let us forget about the super and subscript identifying the reference frames for this quaternion for the sake of clarity, and let us work out Eq. 48 in order to obtain the more canonical equation of the process model. In the previous equation ω is the **actual** angular velocity in body coordinates. The relationship between this angular velocity and the one measured by a gyroscope ω^m with zero-mean normal additive noise ϵ_k at time k is given by:

$$\omega_k^m = \omega_k + \epsilon_k \quad (49)$$

Let us then call $\Omega(\omega)$ the “derivative matrix” which appears in the multiplication of a matrix by a quaternion and has the same structure:

$$\Omega(\omega) = \begin{bmatrix} 0 & -\omega^T \\ \omega & -S(\omega) \end{bmatrix} \quad (50)$$

The discrete-time solution to Eq. 48 is known to be:

$$q_{k+1} = \Phi_k q_k \quad (51)$$

Under the assumption that ω is constant over the integration time (T_s), thus making Ω independent of time, the differential equation becomes time-invariant and a closed form solution can be obtained resulting in the so-called “zeroth order quaternion integrator” , thus:

$$\Phi_k = \exp\left(\frac{1}{2}\Omega(\omega)T_s\right) \quad (52)$$

Using the Taylor expansion of this matrix exponential along with the power properties of matrix $\Omega(\omega)$, you get the common Taylor series expansions of the *sine* and *cos* functions and taking the first order approximation (as $\omega \rightarrow 0$) we finally obtain:

$$\Phi_k = I_{4 \times 4} + \frac{T_s}{2}\Omega(\omega) \quad (53)$$

In this simplified case of the filter, since we are not estimating ω , but measuring it with the gyroscope which is subject to error and bias, the transition matrix that uses ω_m instead of ω will differ from Φ_k by $\Delta\Phi_k$, that is:

$$\Phi_k^m = \Phi_k + \Delta\Phi_k \quad (54)$$

$\Delta\Phi_k$ is called the Error Matrix which according to can be expressed as its matrix power series first order term only, or from the first order approximations of Φ_k^m and Φ_k , such that:

$$\Phi_k^m - \Phi_k = (I_{4 \times 4} + \frac{1}{2}\Omega(\omega_k^m)T_s) - (I_{4 \times 4} + \frac{1}{2}\Omega(\omega_k)T_s) \quad (55)$$

$$= \frac{1}{2}\Omega(\omega_k^m - \omega_k)T_s \quad (56)$$

$$= \frac{1}{2}\Omega(\epsilon_k)T_s = E_k T_s \quad (57)$$

Where ϵ_k is the gyro measurement noise vector, thus:

$$\Delta\Phi_k \simeq E_k T_s \quad (58)$$

Where

$$E_k = \frac{1}{2} \begin{bmatrix} 0 & -\epsilon_k^T \\ \epsilon_k & -S(\epsilon_k) \end{bmatrix} \quad (59)$$

And $S(\epsilon_k)$ the skew-symmetric matrix:

$$S(\epsilon_k) = \begin{bmatrix} 0 & -\epsilon_{k3} & \epsilon_{k2} \\ \epsilon_{k3} & 0 & -\epsilon_{k1} \\ -\epsilon_{k2} & \epsilon_{k1} & 0 \end{bmatrix} \quad (60)$$

Hence, from Eq. 54

$$\Phi_k = \Phi_k^m - \Delta\Phi_k \quad (61)$$

$$\Phi_k = \Phi_k^m - E_k T_s \quad (62)$$

Substituting in Eq. 51

$$q_{k+1} = \Phi_k q_k \quad (63)$$

$$q_{k+1} = (\Phi_k^m - E_k T_s) q_k \quad (64)$$

$$q_{k+1} = \Phi_k^m q_k - T_s E_k q_k \quad (65)$$

The term $E_k q_k$ can be further expanded taking advantage of the properties of the matrix E_k , which when pre-multiplying a quaternion respects the following property ($\Omega(\omega)$ and E_k have the same structure!):

Thus, Eq. 65 can be further expressed as:

$$q_{k+1} = \Phi_k^m q_k - \frac{T_s}{2} \Xi(q_k) \epsilon_k \quad (66)$$

Taking $x = \epsilon$ and $q = q_k$. Finally, the **Process Model** is:

$$x_{k+1} = q_{k+1} = \Phi_k^m q_k + w_k \quad (67)$$

Where:

$$\Phi_k^m = I_{4 \times 4} + \frac{T_s}{2} \Omega(\omega_k^m) \quad (68)$$

$$w_k = -\frac{T_s}{2} \Xi(q_k) \epsilon_k \quad (69)$$

$$\Xi(q_k) = \begin{bmatrix} -q_v^T \\ q_1 I_{3 \times 3} + S(q_v) \end{bmatrix} \quad (70)$$

The zero-mean gyro noise vector ϵ_k is normally distributed, i.e. $\epsilon \sim \mathcal{N}(0, \sigma_g)$

$$\Sigma_k^g = \sigma_g^2 I_{3 \times 3} \quad (71)$$

With process covariance matrix given by:

$$Q_k^w = E(w_k w_k^T) = \left(\frac{T_s}{2} \right)^2 \Xi_k \Sigma_k^g \Xi_k^T \quad (72)$$

Remember that T_s must be kept small, as well as ϵ_k since these assumptions allowed for the approximation of $\Delta\Phi_k$, the Error Transition Matrix first order approximation.

5.1.3 Measurement Model

$[z_k = h(x_{k+1}) + v_k]$. This model is constituted by the accelerometer only, neglecting its bias and scaling factors or body acceleration. The latter assumption is also done in many

commercial IMUs as the one used to compare our results. The measurement model in the body frame:

$$z_k = h(q_{wk+1}^s) + v_k \quad (73)$$

$$z_k = R(q_{wk+1}^s)g^w + v_k \quad (74)$$

Where $R(q_{wk+1}^s)$ is the rotation matrix representing the orientation of the sensor reference frame with respect to the world frame. This rotation matrix is a function of the quaternion orientation. g^w is the gravity vector (as it would be measured by the accelerometer) in Earth coordinates and is considered constant and equal to $[0 \ 0 \ 9.8]^T$. The covariance matrix of the measurement model is assumed constant and equal to:

$$\Sigma_k^a = \sigma_a^2 I_{3 \times 3} \quad (75)$$

5.1.4 Filter design

The measurement model described by Eq. 5.1.3 is non-linear in q . To fully describe the filter we further need to linearize $h(q_{wk+1}^s)$. Notice that the process model given by Eq. 67 is already linear in q .

To linearize Eq. 5.1.3 we proceed to compute the Jacobian of $h(q)$, evaluated at the most recent estimate of q . Let us recall here that $R(q_w^s)$ can be expressed in terms of the quaternion as:

$$R(q_w^s) = \begin{bmatrix} 2q_1^2 - 1 + 2q_2^2 & 2q_2q_3 - 2q_1q_4 & 2q_2q_4 + 2q_1q_3 \\ 2q_2q_3 + 2q_1q_4 & 2q_1^2 - 1 + 2q_3^2 & 2q_3q_4 - 2q_1q_2 \\ 2q_2q_4 - 2q_1q_3 & 2q_3q_4 + 2q_1q_2 & 2q_1^2 - 1 + 2q_4^2 \end{bmatrix} \quad (76)$$

The observation matrix is then defined by the following Jacobian:

$$H_{k+1} = \left. \frac{\partial h}{\partial q} \right|_{x_{k+1|k}} \quad (77)$$

$$= \left. \frac{\partial}{\partial q} R(q_w^s)g^w \right|_{x_{k+1|k}} \quad (78)$$

Where

$$\frac{\partial}{\partial q} R(q_w^s) = \begin{bmatrix} \frac{\partial}{\partial q_1} R(q) & \frac{\partial}{\partial q_2} R(q) & \frac{\partial}{\partial q_3} R(q) & \frac{\partial}{\partial q_4} R(q) \end{bmatrix} \quad (79)$$

with

$$\frac{\partial}{\partial q_1} R = 2 \begin{bmatrix} 2q_1 & -q_4 & q_3 \\ q_4 & 2q_1 & -q_2 \\ -q_3 & q_2 & 2q_1 \end{bmatrix} \quad (80)$$

$$\frac{\partial}{\partial q_2} R = 2 \begin{bmatrix} 2q_2 & q_3 & q_4 \\ q_3 & 0 & -q_1 \\ q_4 & q_1 & 0 \end{bmatrix} \quad (81)$$

$$\frac{\partial}{\partial q_3} R = 2 \begin{bmatrix} 0 & q_2 & q_1 \\ q_2 & 2q_3 & q_4 \\ -q_1 & q_4 & 0 \end{bmatrix} \quad (82)$$

$$\frac{\partial}{\partial q_4} R = 2 \begin{bmatrix} 0 & -q_1 & q_2 \\ q_1 & 0 & q_3 \\ q_2 & q_3 & 2q_4 \end{bmatrix} \quad (83)$$

At this point we have all the elements necessary to implement an Extended Kalman Filter with linearized measurement equations.

5.1.5 Floating-base attitude estimation

In order to estimate the final attitude of the floating base, we proceed by composing the estimate given by the extended Kalman filter of the previous section with the kinematic information of the supporting leg. The floating base attitude will be expressed in w

$$R_{FB}^w = (R_s^{FB} R_w^s(q)) \quad (84)$$

Where q is the quaternion estimated as done in the previous section expressing the orientation of w in s .

5.1.6 Implementation and experiments

A YARP-based C++ module has been written within the CoDyCo software CoDyCO software reference and link to wholeBodyEstimator. The module is called `wholeBodyEstimator`. A class diagram depicting the design principles behind it is shown in Figure 8. The module allows the user to specify the estimators that will be run, in a factory design pattern manner. The list of estimators to be instantiated by the module can be specified via the module's configuration file.

5.2 Estimation of the floor compliance

This section presents preliminary results on the estimation of the force distribution $f(z)$ of the compliant carpet. The carpet's height is equal to $h = 1 \text{ cm}$.

5.2.1 The setup

Figure 9 shows the experimental setup used for estimating the compliance $f(z)$ associated with the chosen soft carpet. By means of a vise, we push a dynamometer that measures the

Figure 9: Estimation setup

Figure 10: Estimation setup

force exerted from the compliant carpet to a flat plate attached to the dynamometer's top. The measurement of the carpet's compression is taken by using a high-precision caliper whose resolution is 0.01 mm .

5.2.2 Results

We carried on experiments with two rectangular contact surfaces of different size:

$S1$: $l_1 = 5.01 \text{ cm}$ and $d_1 = 2.01 \text{ cm}$;

$S2$: $l_2 = 5.6 \text{ cm}$ and $d_2 = 3.5 \text{ cm}$.

The measurements are taken so that the contact force spans the range $[0, 265] \text{ N}$ for $S1$ and $[0, 388] \text{ N}$ for $S2$. Figure 10 depicts both the measurements taken for the two different

surfaces and the approximation result. Recall that the force distribution $f(z)$ is estimated from the measurement of the contact force via Eq. (18), i.e.

$$f(z) = \frac{|F_E(z)|}{l_i d_i},$$

with $i \in \{1, 2\}$. Hence, Figure 10 points out the following facts:

- Assumption 1.1, namely the carpet characteristics be uniform, is well-posed. In fact, measurements taken with a larger contact surface show that the governing behavior of the force distribution $f(z)$ does not change significantly versus the contact's surface.
- The assumption made in Lemma 1 on the linearity of the force distribution versus $(h - z)$ is well-posed.
- Since the carpet is of $h = 1 \text{ cm}$, it shows some nonlinear effects around $(h - z) \approx 0.6 \text{ cm}$. This threshold, which impairs the use of the model (21) to evaluate the total force-torque acting on the plate, is far from the operational condition representing a foot size in contact with the carpet.

Appendix

Proof of Lemma 1

First, note that any point $p = (x, y, z)$ of the rectangular surface can be expressed as follows

$$p = p_M + Rp', \quad (85)$$

where R is the rotation matrix given by $R = (i, j, n)$, and $p' = (u, v, 0)$ any point of the rectangular surface expressed in the frame (p_M, R) , which implies that $u \in [-\frac{l}{2}, \frac{l}{2}]$ and $v \in [-\frac{d}{2}, \frac{d}{2}]$. Then, we consider (85) as a variable change

$$x = x(u, v) \quad (86a)$$

$$y = y(u, v) \quad (86b)$$

to facilitate the process of finding the solutions to the integrals (19). Let us remind that given a double integral of a function $g(x, y) : \mathbb{R}^2 \rightarrow \mathbb{R}$, a variable change of the form (86) yields

$$\int \int g(x, y) dx dy = \int \int g(x(u, v), y(u, v)) |\det(J)| du dv, \quad (87)$$

where J is the Jacobian of the variable transformation (86), i.e.

$$J = \begin{pmatrix} \partial_u x & \partial_v x \\ \partial_u y & \partial_v y \end{pmatrix} \quad (88)$$

It is straightforward to verify that the variable change (85) yields

$$|\det(J)| = |i_1 j_2 - i_2 j_1| = |n^\top e_3| \quad (89)$$

Once the variable change (86) has been applied, the domains on which the integrals (19) must be evaluated are normal with domains $u \in [-\frac{l}{2}, \frac{l}{2}]$ and $v \in [-\frac{d}{2}, \frac{d}{2}]$. Hence, from Eqs. (19) (21) (85) and (89), one has

$$F = e_3 k |n^\top e_3| \int_{-\frac{d}{2}}^{\frac{d}{2}} dv \int_{-\frac{l}{2}}^{\frac{l}{2}} (h - z_M - i_3 u - j_3 v) du, \quad (90a)$$

$$M = k |n^\top e_3| \int_{-\frac{d}{2}}^{\frac{d}{2}} dv \int_{-\frac{l}{2}}^{\frac{l}{2}} (h - z_M - i_3 u - j_3 v) S(p_M - \bar{p} + u i + v j) e_3 du. \quad (90b)$$

By computing the above integrals, one gets (22).
